## Structural locations of the iron ions in cordierite: a spectroscopic study

Received: 27 June 2000 / Accepted: 28 November 2000 / Published online: 3 May 2001  
© Springer-Verlag 2001

**Abstract** A series of 21 cordierites with  $0.06 < \text{Fe}^{2+}$  cations pfu  $< 1.54$  from different petrogenetic environments were studied by polarized electronic absorption single-crystal spectroscopy and  $^{57}\text{Fe}$  Mössbauer spectroscopy (MS). The electronic spectra measured in the range  $35,000\text{--}1,000\text{ cm}^{-1}$  using microscope techniques were also obtained at different temperatures between 80 and 700 K on five different samples. The aim of this study was to answer the still-debated question of the location of iron in the cordierite structure. Both electronic absorption and  $^{57}\text{Fe}$  Mössbauer spectra confirm the presence of  $\text{Fe}^{2+}$  on two different structural positions. The major fraction, 90–99% of the total  $\text{Fe}^{2+}$ , occupies the octahedral site  $8g$  in orthorhombic cordierite. Minor amounts of  $\text{Fe}^{2+}$  occur in a second, non-octahedral site. The octahedral and non-octahedral  $\text{Fe}^{2+}$  give rise to two MS doublets and to different absorption bands in the electronic absorption spectra, namely  $\nu_1$  and  $\nu_2$  at about  $8,300$  and  $10,000\text{ cm}^{-1}$  both of which are  $\alpha$ -polarized for octahedral  $\text{Fe}^{2+}$ , and  $\beta/\gamma$ -

polarized  $\nu_3$  at about  $10,500\text{ cm}^{-1}$  for non-octahedral  $\text{Fe}^{2+}$ . The integral intensities of the  $\nu_1$  and  $\nu_2$  bands increase linearly with increasing total iron contents. Their energies decrease slightly with increasing  $\text{Fe}^{2+}$ . Increasing temperature causes a shift of  $\nu_1$  to lower energies, while the integral intensities of  $\nu_1$  and  $\nu_2$  increase. These observations permit an assignment of the  $\nu_1$  and  $\nu_2$  bands to transitions derived from the  ${}^5\text{T}_{2g} \rightarrow {}^5\text{E}_g$  transition of octahedral  $\text{Fe}^{2+}$ . The integral intensity of the  $\beta$ - and  $\gamma$ -polarized  $\nu_3$  band correlates linearly with the concentration of non-octahedral  $\text{Fe}^{2+}$ . Its high molar extinction coefficient, ca.  $150\text{ cm}^{-2}\text{ l mol}^{-1}$ , and temperature independence are best explained by its assignment to  $dd$  transitions of  $\text{Fe}^{2+}$  in tetrahedral coordination. There occurs also a broad band at  $18,000\text{ cm}^{-1}$  polarized predominantly along  $b$ . Its properties are typical of a metal–metal charge transfer (CT) band involving  $\text{Fe}^{2+}$  on the octahedra and  $\text{Fe}^{3+}$  on the  $\text{T}_1\text{I}$ -tetrahedra, the two of which are edge-shared. All spectroscopic data, including changes in the electronic spectra caused by heating at  $1,000\text{ }^\circ\text{C}$  in air, as well as crystal-chemical considerations, suggest that the ring-connecting  $\text{T}_1\text{I}$ -tetrahedra contain small amounts of  $\text{Fe}^{2+}$ .

### Introduction

The structural location and valence state of the iron ions in cordierite are of interest to mineralogists and ceramists. They are important because of their effect on thermodynamic calculations, their possible influence on the low thermal expansion of cordierite, their role in the origin of the spectacular pleochroism of the mineral, and, finally, because of their significance in explaining the crystallochemical features of a variety of silicate structures possessing infinite channels formed by the stacking of six-membered (Si, Al) tetrahedral rings.

Cordierite is a framework aluminosilicate with the general formula  $(\text{Mg}, \text{Fe})_2\text{Al}_4\text{Si}_5\text{O}_{18}\cdot n(\text{H}_2\text{O}, \text{CO}_2)$ . It is common in low- and medium-pressure metapelitic rocks of amphibolite and granulite facies. The crystal structure

(Gibbs 1966) of most natural cordierites is orthorhombic of space group  $Cccm$  with four formula units per unit cell. It contains distorted six-membered corner-shared tetrahedra rings. The tetrahedra have centres at the Wyckoff position  $8l$  of site symmetry  $m$ , but with different atomic coordinates giving two pairs of  $T_{23}$  and  $T_{21}$  Si-tetrahedra and two  $T_{26}$  Al-tetrahedra (Fig. 1a, the labelling of the sites follows Hochella et al. 1979). The rings are stacked over each other along  $[001]$  and interconnected by  $T_{11}$  Al-tetrahedra on  $8k$  of site symmetry 2, and Si-tetrahedra  $T_{16}$ , on  $4b$  of point symmetry  $222$  (Fig. 1a, b). The octahedral ions are on the  $8g$  position of point symmetry 2. The stacking of the tetrahedral rings along  $[001]$  produces infinite channels parallel to  $c$ , which can contain atoms and molecules. Two types of channel positions are shown in Fig. 1, Ch0 at  $4a$  of point symmetry  $222$  (Fig. 1b) and Chw at  $8h$  of site symmetry 2 (Fig. 1c).

Since Duncan and Johnston (1974) first determined in a Mössbauer study on oriented cordierite crystals that a minor amount of divalent iron is located on a non-octahedral site, there has been ongoing discussion regarding this possible site. Goldman et al. (1977) proposed that a band at  $10,500\text{ cm}^{-1}$  in the  $\beta$ - and  $\gamma$ -polarized electronic spectra of cordierite originates from non-octahedral  $\text{Fe}^{2+}$ . It is accepted that this absorption band and the “non-octahedral”  $\text{Fe}^{2+}$  doublet in the Mössbauer spectra are a result of a minor  $\text{Fe}^{2+}$  fraction located on the same structural site. This conclusion is supported by changes in the Mössbauer and electronic spectra observed after heating samples above  $500\text{ }^\circ\text{C}$ . Both methods show a similar increase in the octahedral to non-octahedral ferrous iron ratio after heating (Vance and Price 1984).

Different sites have been suggested for this minor non-octahedral  $\text{Fe}^{2+}$  (Duncan and Johnston 1974; Pollak 1976; Goldman et al. 1977; Vance and Price 1984; Geiger et al. 2000a). Two general views exist. One group believes that this  $\text{Fe}^{2+}$  is located in the channels (Duncan and Johnston 1974; Goldman et al. 1977; see Fig. 1b and c). A second group has proposed a tetrahedral position for this non-octahedral  $\text{Fe}^{2+}$  (Vance and Price 1984; Geiger et al. 2000a). Although these two kinds of sites are very different crystal-chemically (e.g. Armbruster 1986), the controversial interpretations of the spectroscopic results demonstrate that the experimental data are insufficient for unequivocal conclusions. Additional data, including results on the temperature, polarization and composition behaviour of the electronic absorption bands and Mössbauer spectra, measured on the same set of cordierite samples, are necessary to differentiate between the possible structural locations of the non-octahedral  $\text{Fe}^{2+}$ .

Although natural cordierites display a range of Fe–Mg substitution and the structure allows other substitutions involving ions of different charges, recent investigations show very low contents of ferric ions (e.g. Geiger et al. 2000a, 2000b). On the other hand, Faye et al. (1968) showed that the impressive violet-blue ( $\beta$ -

$\gamma$ -polarizations) to orange ( $\alpha$ -polarization) pleochroism typical of cordierite, is caused by  $\text{Fe}^{2+}\text{Fe}^{3+}$  CT. Here again, a determination of the site and the concentrations of  $\text{Fe}^{3+}$  are not possible by standard chemical and X-ray diffraction methods. The main experimental tools that can provide information on these questions are spectroscopic methods, especially single-crystal electronic spectroscopy.

**Fig. 1** Sections of the cordierite structure. Possible  $\text{Fe}^{2+}$ -polyhedra are shown in black, the Al-tetrahedra are shaded grey. Some tetrahedra are omitted in the projections **b** and **c** for clarity. **a** Structure projection onto  $(001)$ ; **b** channel position  $(000)$  in the centre of a six-membered ring; **c** “wall” position in the channel after Duncan and Johnston (1974). The optical polarization directions  $\alpha$ ,  $\beta$  and  $\gamma$  are parallel to  $c$ ,  $b$  and  $a$  respectively

This study was undertaken to determine the site locations of Fe<sup>2+</sup> and Fe<sup>3+</sup> in cordierite using a combination of single-crystal electronic (80 K to 700 K) and Mössbauer spectroscopic measurements and crystal-chemical data obtained on a well-characterized series of natural cordierites from different petrologic environments and of different composition.

## Experimental methods

### Sample description and preparation

Cordierite samples from 21 different localities and rocks types, most of which are described in the literature, were studied using single-crystal electronic absorption and Mössbauer spectroscopic methods. For some samples the PT conditions of formation, based mostly on the garnet–cordierite equilibrium (e.g. Kurepin 1991), are known. These data are summarized in Table 1.

Fragments of cordierite crystals were separated from the rock samples and oriented parallel to (100), (010) and/or (001) using their conoscopic interference figures. Then they were ground and polished on both sides to a thickness of 0.1–0.5 mm. The platelets obtained were used for measurements of the single-crystal polarized electronic spectra and for electron microprobe studies. The latter were performed on those areas on which the electronic spectra were recorded. The compositions are presented in Table 2. The remaining cordierite material was ground into a powder for a measurement of the <sup>57</sup>Fe Mössbauer spectra.

Conditions and standards used for the electron microprobe analyses are described in Khomenko et al. (1994) and Langer and Khomenko (1999).

### Single-crystal electronic absorption spectroscopy

The polarized spectra with E//a ( $\gamma$ -spectra), E//b ( $\beta$ -spectra) and E//c ( $\alpha$ -spectra) were measured at room temperature in the spectral range 35,000–1,000 cm<sup>-1</sup> by means of a single-beam microscope spectrometer model UMSP 80 from Zeiss (35,000–

12,000 cm<sup>-1</sup>) and a Bruker FTIR spectrometer IFS 66 (13,000–1,000 cm<sup>-1</sup>) with an IR-microscope attachment. For the Zeiss spectrometer, a 10× Ultrafluars served as the objective and condenser. The measuring diameter was 32  $\mu$ m, the spectral slit width and step width were both 1 nm. With the FTIR-Bruker spectrometer, equipped with an IR-microscope and polarizer, the polarized spectra were obtained with a measuring diameter of 90  $\mu$ m and a spectral resolution of 2 cm<sup>-1</sup>. Further experimental details are given in Langer (1988).

Curve deconvolution of overlapping absorption bands was done with the program OPUS 2.2 using the approach described in Geiger et al. (2000a). Different deconvolutions using the same procedure gave differences in band positions of less than 0.4%. The crystal field parameter Dq was extracted from the spectra using the same estimation of the ground T-level splitting as in Langer and Khomenko (1999).

Five samples, numbers 3, 9, 14, 17 and 21 in Table 1, were chosen for spectroscopic measurement at low (80 K) and high (500 and 700 K) temperatures. These measurements were performed on both spectrometers with an accuracy of  $\pm 10$  using a Linkam THMS 600 heating–freezing stage equipped with a TP 92 temperature controller. A gold grating placed on the heating–cooling cell served as a sample holder. Reference spectra were measured through the Linkam stage at the same temperature. The scanning and fitting procedures were the same as those of the room-temperature measurements. The temperatures of the crystals could not be measured directly. However, differences between the sample and the heating–freezing cell are probably less than 10 K, which will affect the spectra negligibly.

### <sup>57</sup>Fe Mössbauer spectroscopy

The Mössbauer spectra of 15 cordierites were measured at room temperature and/or 77 K with a nominal 50 mC <sup>57</sup>Co/Rh source using a 512 multi-channel analyser. The low-temperature measurements were made with an Oxford cryostat. Cordierite powders were pressed together with corn starch into pellets with approximately 5 mg Fe<sup>2+</sup> per cm<sup>3</sup>. The spectra were fitted to either one or two symmetric doublets with the program MÖSALZ, (W. Lottermoser, personal communication). Isomer shifts are given relative to metallic iron. More details can be found in Geiger et al. (2000a).

## Results and discussion

### Cordierite compositions and crystal-chemical correlations

The compositions of 14 of the 21 cordierites show a slight excess, up to 0.1 atom pfu, of divalent cations (Mg + Fe + Mn) over the stoichiometric value of 2.0. The fraction of such cordierites would be even greater, if two Li-bearing samples were excluded. Such a cation excess is common in natural cordierites. This observation, together with the deficiency in the number of Si + Al + Be cations in tetrahedral sites, taking into account the minor Be and Li in most samples, suggests the following possible substitutions:

assuming a channel position for minor non-octahedral Fe<sup>2+</sup> and the presence of tetrahedral vacancies in the structure;

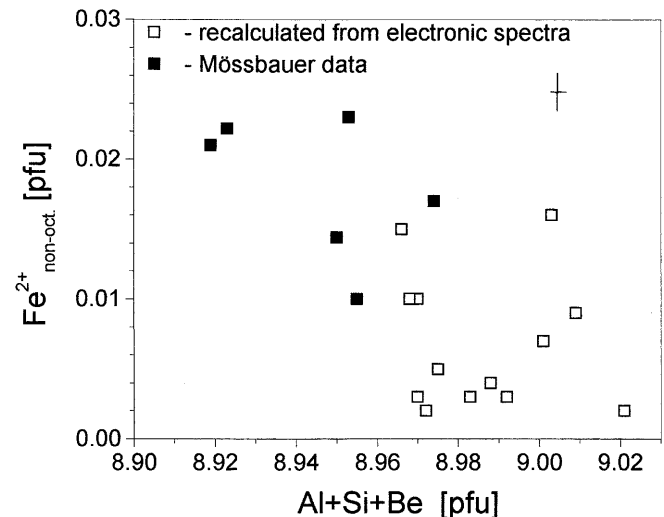

with divalent cations in tetrahedral sites and Na in the channels; or

Energetically, a complete occupancy of framework sites (substitution 2 or 3) should be preferable. A rough negative correlation between non-octahedral Fe<sup>2+</sup> and the sum of the “tetrahedral” ions (Fig. 2) is consistent with any of the substitutions (1), (2) or (3).

Our compositional data show a negative linear correlation between the sum of the divalent octahedral and the sum of the tetrahedral (Al + Si + Be) cations (Fig. 3). The best-fit line nearly intersects the “stoichiometric” point (Mg + Fe + Mn = 2, Al + Si + Be = 9) and describes well

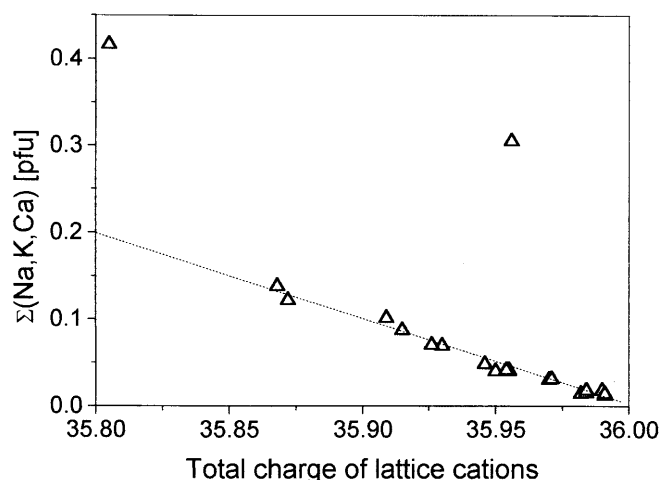

**Fig. 2** Content of non-octahedral Fe<sup>2+</sup> as a function of the sum of the Si + Al + Be tetrahedral cations. An error bar is shown for the Mössbauer data. See text for a calculation of non-octahedral Fe<sup>2+</sup>

**Fig. 3** Sums of the divalent Fe+Mn+Mg cations and channel Na+K+Ca cations versus the sum of the tetrahedral cations

substitutions (2) and/or (3) with a constant sum of 11 lattice cations pfu (Fig. 3). The number of Na, K and Ca channel cations shows, with the exception of two Li, Be-rich samples, a negative correlation versus the total charge of all the lattice cations (Fig. 4), but does not show any correlation versus the sum of the tetrahedral ions. The latter relationship changes its slope at the “stoichiometric” point, from being negative, when there is a tetrahedral cation deficiency, to positive in the case where  $(Al + Si + Be) > 9$  (Fig. 3). These results allow us to determine the importance of substitutions (2) and/or (3) and, therefore, about minor amounts of divalent ions on tetrahedral sites rather than the presence of tetrahedral vacancies in the case where  $(Al + Si + Be) < 9$ . From the rough trend shown in Fig. 2, it can be concluded that  $Fe^{2+}$  enters about one third of the tetrahedra that are not

**Fig. 4** Channel cation sum as a function of the total charge of the lattice cations

occupied by Al, Si or Be. The channel cations compensate for the charge deficiency resulting from substitution (2), when  $(Al + Si + Be) < 9$ , and by the incorporation of tetrahedral Be and/or octahedral Li when  $(Al + Si + Be) > 9$ .

Magnesian cordierites with  $X_{Fe} = Fe/(Fe + Mg) < 0.3$  are typically characterized by slightly lower Al contents and there exists a slight positive correlation between  $X_{Fe}$  and Al. In ferrous-rich samples, the number of Al cations is close to the stoichiometric number of 4 atoms pfu, with only one exception (Fig. 5). This difference between Mg-rich and more Fe-rich cordierites may reflect an inverse relationship that exists between the mean  $T_{11}-O$  bond length and the mean radius of the octahedral cation (Armbruster 1985). It could explain also why there is more tetrahedral  $Fe^{2+}$  in Mg-rich cordierites versus that in Fe-rich samples. In agreement with this, an analysis of the literature data shows a negative correlation between the mean octahedral Me-O distance and the mean T-O distances in the ring-connecting tetrahedra in the structure of double-ring silicates (Bakakin et al. 1975; Cerný et al. 1980; Szymanski et al. 1982; Abraham et al. 1983; Alietti et al. 1994; Armbruster and Oberhänsli 1988a, 1988b; Hawthorne et al. 1991). This reflects a tendency to achieve mutual size compensation between the edge-shared polyhedra.

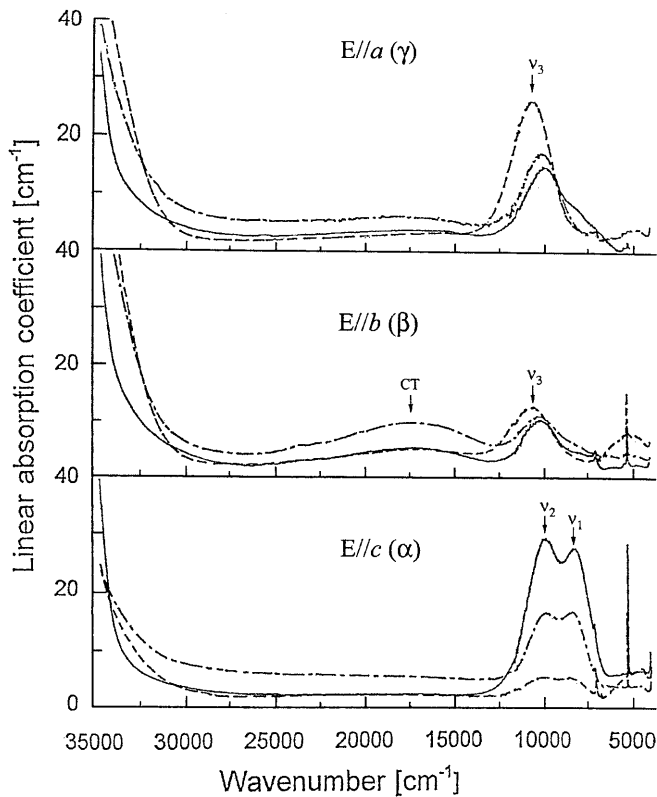

The presence of small amounts of tetrahedral  $Fe^{2+}$ , even in samples which have enough  $(Al + Si + Be)$  to fill all tetrahedral sites (Table 2, Fig. 2), demonstrates a slight disorder of Al and (Fe, Mg) between tetrahedral and octahedral sites. Such disorder is common in structurally similar silicates such as osunilite (e.g. Armbruster and Oberhänsli 1988a).

Room-temperature single-crystal electronic absorption spectra: absorption bands caused by octahedral and non-octahedral  $Fe^{2+}$  ions.

Typical polarized electronic absorption spectra of cordierite are shown in Fig. 6. The  $Fe^{2+}$  ions give rise to a doublet consisting of two overlapping bands,  $\nu_1$  and  $\nu_2$ , located between 11,000 and 8,000  $cm^{-1}$  in the  $\alpha$ -polarized

**Fig. 5** Plot of the number of aluminium cations versus the  $Fe/(Fe + Mg)$  ratio

**Fig. 6** Room-temperature polarized electronic absorption spectra of cordierites 8c6b/004 (no. 5), *dash lines*; 9–81 (no. 17), *dash-dot lines*; and sekaninaite (no. 21), *solid lines*. *a*, *b*, and *c* are the crystallographic directions

spectra ( $E//c$ ), and a strong, single  $v_3$  band near  $10,500\text{ cm}^{-1}$  in the  $\gamma$ - and  $\beta$ -polarized spectra. In the  $\beta$ - and  $\gamma$ -polarized spectra of ferrous-rich cordierites a shoulder at  $8,000\text{ cm}^{-1}$  is observed on the low-energy wing of the  $10,500\text{-cm}^{-1}$ -centred band (Fig. 6, sekaninaite spectra). Its position and correlation with the intensity of the doublet in the  $\alpha$ -polarized spectra support the proposal of Goldman et al. (1977) that it represents a component of a non-fully polarized low-energy  $v_1$  band of the doublet, which is most intense in the  $\alpha$ -spectra. The energies of all three bands decrease with increasing total iron content. The bands shift by  $-300$  ( $v_1$ ),  $-500$  ( $v_2$ ) and  $-900\text{ cm}^{-1}$  ( $v_3$ ) over the compositional range  $0.06\text{--}1.54\text{ Fe}^{2+}$  pfu (Table 3, Fig. 7a). The integral intensities of the doublet ( $A_1 + A_2$ ), and each of its two bands, are proportional to the total Fe content, while the intensity of the  $v_3$  band shows no such correlation (Fig. 7b).

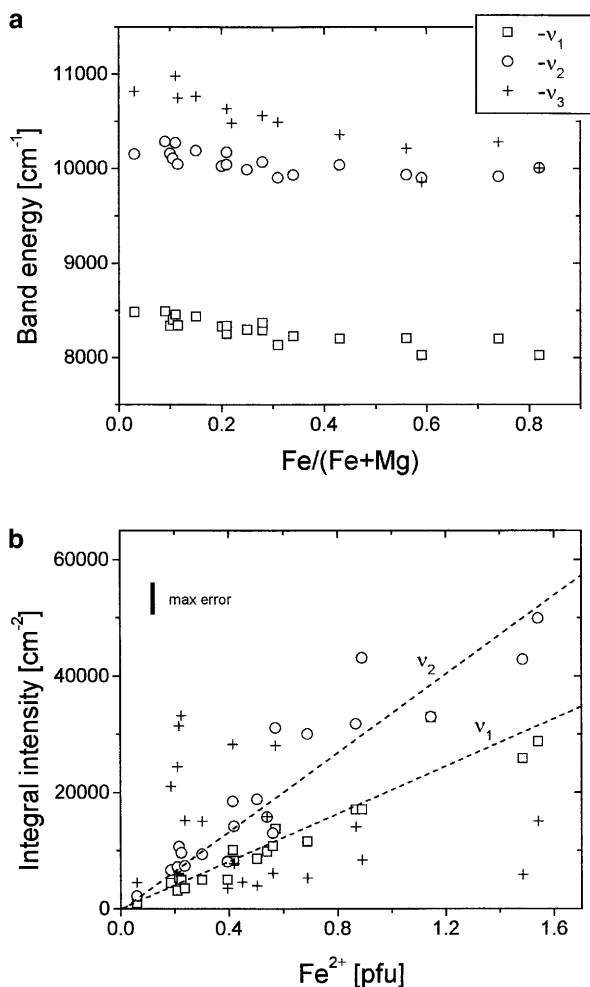

Results of the spectra deconvolution give a constant ratio of  $A_2:A_1 \approx 2$  between the integral intensities of the two components of the  $\alpha$ -polarized doublet over different Fe/Fe + Mg ratios. The half-widths of the  $v_1$  and  $v_2$  bands are  $2,000 \pm 400\text{ cm}^{-1}$  and they show no relationship to composition. The  $v_1$  band at  $8,000\text{ cm}^{-1}$  is narrower than the  $v_2$  and  $v_3$  bands centred near  $10,000\text{ cm}^{-1}$ . These results are consistent with the assignment of the  $\alpha$ -polarized doublet to the spin-allowed transitions of octahedrally coordinated  $\text{Fe}^{2+}$  derived from the  ${}^5\text{T}_{2g} \rightarrow {}^5\text{E}_g$  transition in an  $O_h$ -symmetry field (Goldman et al. 1977).

X-ray diffraction results define a point symmetry 2 for the octahedral 8g site with a twofold axis parallel to *a* (Fig. 1a). This symmetry completely removes the de-

**Table 3** Energies ( $\nu$ ,  $\text{cm}^{-1}$ ), half-widths ( $hw$ ,  $\text{cm}^{-1}$ ) and integral intensities ( $A$ ,  $\text{cm}^{-2}$ ) of electronic absorption bands in the polarized spectra of the cordierite samples measured at room temperature. Errors are estimated to be less than 1% for the energies, and less

than 10% for their half-widths and integral intensities. *n.m.* denotes no spectra were measured. *Dash* indicates that no CT bands were observed

**Fig. 7** **a** Energies of the  $\text{Fe}^{2+}$  absorption bands near  $10,000 \text{ cm}^{-1}$  as a function of  $\text{Fe}/(\text{Fe}+\text{Mg})$ .  $v_1$  and  $v_2$  are as fitted from the  $\alpha$ -polarized spectra, and  $v_3$  from the  $\gamma$ -polarized spectra. Errors are equal to or smaller than the symbol size. **b** Integral band intensities versus  $\text{Fe}^{2+}$  pfu

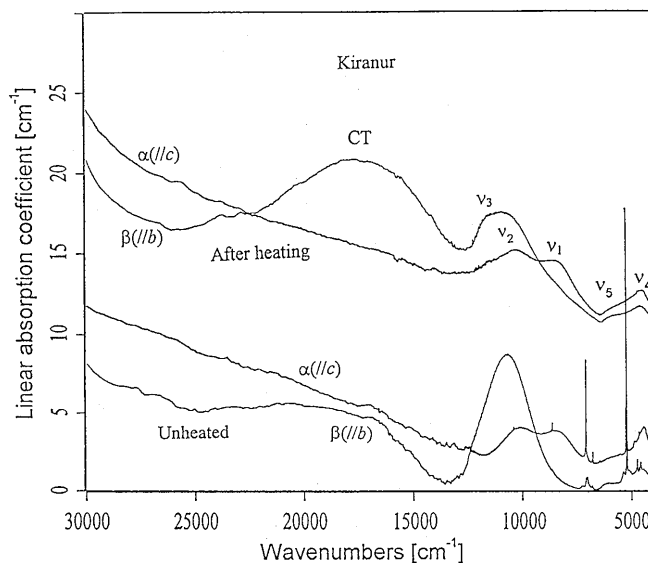

generacy of the E and T electronic states. As a result, two bands should appear in the electronic absorption spectra due to transitions between the split ground  ${}^5\text{T}_{2g}$  and the upper  ${}^5\text{E}_g$ -level, both of which are polarized either parallel or perpendicular to the twofold axis (e.g. Marfunin 1979). In cordierite spectra, however, the doublet is only present in  $\alpha$ -polarization (Fig. 6). This could be a result of a pseudo-symmetry higher than 2, e.g. 3, with the main trigonal axis parallel to  $c$ . The higher effective point symmetry gives rise to selection rules and a corresponding polarization of the electronic transitions consistent with the main geometrical distortion of the octahedra, which are strongly compressed along the pseudo-triad axis parallel to  $c$  (e.g. Gibbs 1966).

A very broad band centred at about  $18,000 \text{ cm}^{-1}$ , with a  $\beta/\gamma$  intensity ratio of 2.6–2.9, is often present in the  $\beta$ - and  $\gamma$ -polarized spectra of cordierite (Fig. 6). Its intensity differs strongly between the samples, showing no correlation with the total Fe content, nor with the intensities of the  $\text{Fe}^{2+}$  bands between 11,000 and

$8,000 \text{ cm}^{-1}$ . Because it shows all the characteristics of a CT absorption band, i.e. a large half band width of  $6,000\text{--}8,000 \text{ cm}^{-1}$ , energy, thermal behaviour and polarization, it was assigned to  $\text{Fe}^{2+}\text{Fe}^{3+}$  CT (Faye et al. 1968; Smith and Strens 1976; Goldman et al. 1977). However, there is no consensus concerning where the corresponding iron ions reside. Several weak and narrow absorption peaks are superimposed upon the CT band; the most prominent of them are located at about 20,300, 22,700, 23,800 and  $25,000 \text{ cm}^{-1}$  (Figs. 6, 8). Their energies, intensities and widths are typical of quintet–triplet spin-forbidden  $\text{Fe}^{2+}$  bands as observed in the spectra of other silicates (e.g. Langer and Abu-Eid 1977; Khomenko and Platonov 1987).

The electronic absorption spectroscopic results are summarized in Table 3. The accuracy of the band parameters depends on the curve-fitting procedures adopted, especially on the background used in the fitting. In the case here (Geiger et al. 2000a), errors are estimated to be less than 1% for the band positions and less than 10% for their half-widths and integral intensities.

Sharp, intense bands, related to internal vibrations of molecular  $\text{H}_2\text{O}$ , are observed between  $3,000$  and  $4,000 \text{ cm}^{-1}$ . They are superimposed on a weak and broad absorption feature located between  $4,000$  and  $6,000 \text{ cm}^{-1}$ , which is a single band or a band envelope, whose position and polarization cannot be precisely defined due to the strong deformation caused by the intense  $\text{H}_2\text{O}$  stretching bands. Its energy, its correlation in intensity with the  $\beta/\gamma$ -polarized  $v_3$  band at  $10,500 \text{ cm}^{-1}$  and its polarization were given as evidence for minor channel  $\text{Fe}^{2+}$  (Goldman et al. 1977). This feature was analysed after the  $\text{H}_2\text{O}$  bands were subtracted from the spectra. However, no reasonable quantitative information on band energy, half-width and intensity could be obtained.

**Fig. 8**  $\alpha$ - and  $\beta$ -polarized electronic absorption spectra of the Kiranur (no. 3) cordierite before and after heating in air at  $1,000 \text{ }^\circ\text{C}$  for 10 h

In contrast to the data of Goldman et al. (1977), most spectra show the presence of two weak bands in this region: a  $\nu_4$  band at 4,500–5,000  $\text{cm}^{-1}$ , predominantly  $\alpha$ -polarized, and a  $\nu_5$  band at 6,000  $\text{cm}^{-1}$ , predominantly  $\beta$ -polarized. The more intense  $\nu_4$  band occurs at higher energies in iron-rich samples, whereas the  $\nu_5$  band does not show any change in its spectral position. The intensities of both resolved bands correlate neither with those of the  $\nu_3$  band at 10,500  $\text{cm}^{-1}$ , nor with the  $\alpha$ -polarized  $\nu_1$ ,  $\nu_2$  doublet.

To get more information on this weak absorption feature, one crystal of the Kiranur cordierite (no. 3 in Table 1) was heated in air at 1,000 °C for 10 h and then quenched, and its electronic spectra were measured. Its spectra before and after heating are compared in Fig. 8. Because dehydration occurs at 800 °C (e.g. Goldman et al. 1977; Vance and Price 1984), the spectra of the heated sample do not show any  $\text{H}_2\text{O}$  bands and the two-band structure of the envelope at 5,000  $\text{cm}^{-1}$  is observed more clearly. The intensity of the  $\nu_3$  band decreases by a factor of about three upon heating, while no changes can be observed in the intensities of the  $\alpha$ -polarized doublet at 10,000  $\text{cm}^{-1}$  or the two bands near 5,000  $\text{cm}^{-1}$  (Fig. 8). Since  $\text{Fe}^{2+}$  is the only transition metal ion which can be responsible for absorption in the infrared region, and the energies of both bands near 5,000  $\text{cm}^{-1}$  are too high for transitions between the levels derived from the split lower T-state of  $\text{Fe}^{2+}$  in octahedra (e.g. Langer and Khomenko 1999), a possible explanation for their origin is through the presence of a minor  $\text{Fe}^{2+}$  fraction in a non-octahedral position.

The existence of the  $\nu_3$  band after complete dehydration is at odds with the proposal of non-octahedral channel  $\text{Fe}^{2+}$  that has the oxygen of the water molecule as a ligand. The fivefold channel site (Duncan and Johnston 1974) or the site that includes the six oxygen atoms in the tetrahedral rings, plus one or two overlying and/or underlying oxygens of channel water (Fig. 1b, c), would be destroyed during dehydration. In both of these cases, any corresponding non-octahedral  $\text{Fe}^{2+}$  would experience a change in its coordination. Therefore, the  $\nu_3$  absorption band should disappear and new bands at other energies and with other polarizations should arise in the spectra after heating. This, however, does not occur (Fig. 8). The same arguments lead to the conclusion that the weak  $\nu_4$  and  $\nu_5$  bands also originate from  $\text{Fe}^{2+}$  ions which have no water in their first coordination sphere. Because of their weakness and an uncertainty of their intensities, it is difficult to determine their relationship with the non-octahedral  $\text{Fe}^{2+}$  which gives rise to the strong  $\nu_3$  band.

Electronic absorption spectra measured at low and high temperatures: local structural characterization of the sites occupied by  $\text{Fe}^{2+}$

The electronic absorption bands behave differently upon heating from 80 to 700 K depending upon the nature and the local symmetry of the corresponding structural

sites. Generally, with increasing temperature all three bands in the 10,000  $\text{cm}^{-1}$  region show changes that are typical of  $\text{Fe}^{2+}$   $dd$  bands: that is a broadening, shifts to lower energies and, in the case of the  $\nu_1$  and  $\nu_2$  bands, an increase of integral intensities (Fig. 9, Table 4). The bands of octahedral  $\text{Fe}^{2+}$  shift to lower energies, with the  $\nu_1$  band showing a larger T-dependence (ca.  $-1 \text{ cm}^{-1} \text{ grad}^{-1}$ ) than the  $\nu_2$  band (Fig. 10a). This can be related to changes in the structure following heating, since the energies of the  $\nu_1$  and  $\nu_2$  bands are determined by the crystal field parameter  $Dq$  and the E-state splitting values (Fig. 10b); both the latter are related to the geometry of the structural site containing  $\text{Fe}^{2+}$  (e.g. Burns 1993). A decrease in  $Dq$ , which is related to an increase in the  $\text{Fe}^{2+}$ –O distances, causes a shift to lower energies of both bands that are derived from the  $^5\text{E}$ -state, while an increase of the  $^5\text{E}$ -state split causes the similar effect on the lower level, but moves the upper level to the higher energies. Together, both effects lead to a strong negative temperature dependence of the  $\nu_1$  band and only minor changes of the  $\nu_2$  band position (Fig. 10).

The spectra show that  $Dq$  decreases with increasing temperature by the same amount  $-0.05 \text{ cm}^{-1} \text{ grad}^{-1}$  in ferrous and Mg-rich cordierites (Fig. 10b). We calculate

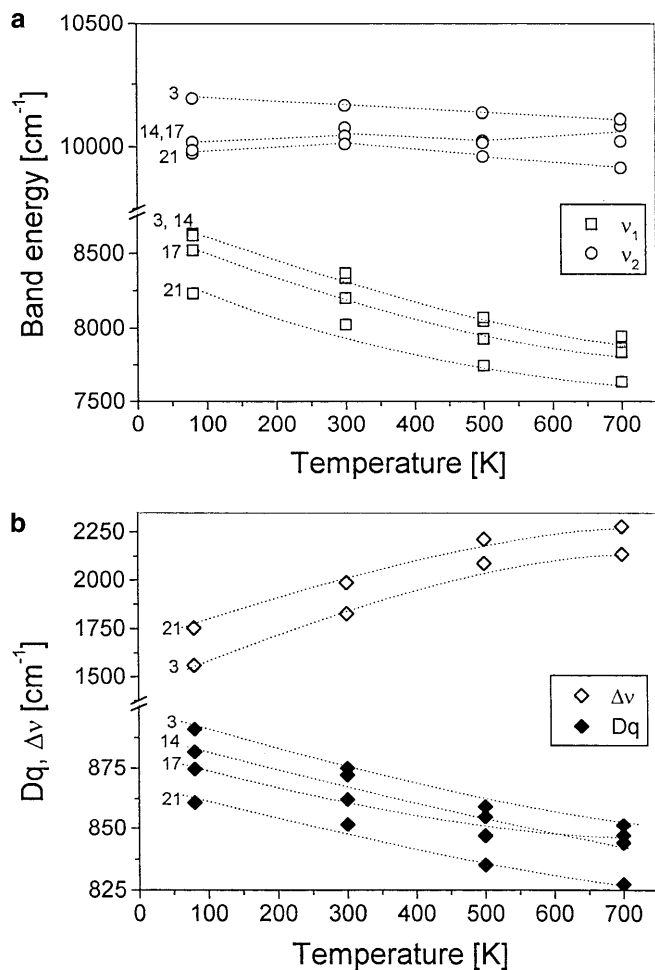

Fig. 9 Polarized electronic absorption spectra of Kiranur (no. 3) cordierite measured at different temperatures

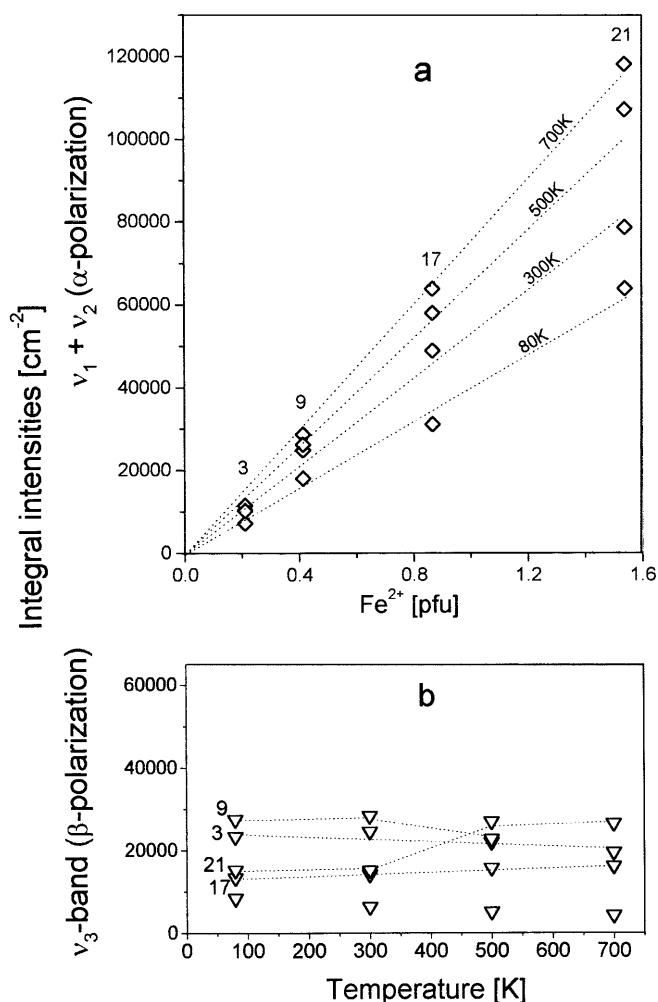

**Fig. 10** Temperature change of the absorption doublet consisting of the  $v_1$  and  $v_2$  bands that are related to  $\text{Fe}^{2+}$  ions in the octahedral site: **a** band energies; **b** crystal field parameter  $Dq$  and the  ${}^5E_g$ -level splitting given as  $\Delta v$ . Sample numbers correspond to the numbers in the tables

a mean local  $\text{Fe}^{\text{VI}}\text{-O}$  thermal expansion of  $12.8 \times 10^{-6} \text{ grad}^{-1}$  using the local  $\text{Me-O}$  distance obtained from 10Dq values (e.g. Langer 2001) and the results obtained from the ferrous-rich sekaninaite (sample no. 21) as a reference. This value is larger than the average octahedral thermal expansion of  $9.3 \times 10^{-6} \text{ grad}^{-1}$  determined from a high-temperature X-ray structure refinement on sekaninaite and it corresponds better to that of a magnesian-rich cordierite ( $12.6 \times 10^{-6} \text{ grad}^{-1}$ ) (Hochella et al. 1979). The same local  $\text{Fe}^{\text{VI}}\text{-O}$  thermal expansion value was determined for all cordierites regardless of their  $\text{Fe}/(\text{Fe} + \text{Mg})$  ratios.

The temperature dependence of the  $v_3$  absorption band is similar to that of the  $v_2$  band showing a slight shift to lower energies with increasing temperature. This is probably related to an increase in the tetrahedral  $\text{Fe}^{2+}\text{-O}$  bond lengths. The possible lower energy  $v_4$  and  $v_5$  components of the excited T electronic state of tetrahedral  $\text{Fe}^{2+}$  were not resolved in the high- and low-temperature spectra.

The integral intensities of the  $v_1$  and  $v_2$  bands increase linearly and nearly double upon heating from 80 to 700 K (Fig. 11a). This behaviour is typical for spin-allowed  $dd$  bands in centrosymmetric crystal fields (e.g. Taran et al. 1994), but can also occur in fields which are slightly distorted from centrosymmetry. It is caused by a weakening of the Laporte selection rules due to a dynamic loss of the symmetry centre  $\bar{1}$  at the  $3d^N$ -ion site at elevated temperatures. On the other hand, the intensity of the  $v_3$  band is nearly independent of temperature (Fig. 11b). This is evidence that the related  $\text{Fe}^{2+}$  ions are located in a non-centrosymmetric crystal field. This is contradictory to the assignment of the  $v_3$  band to  $\text{Fe}^{2+}$  in a centrosymmetric channel position (Goldman et al. 1977) and strengthens the arguments given by Vance and Price (1984) and Geiger et al. (2000a) for tetrahedrally coordinated  $\text{Fe}^{2+}$  ions.

An increase in temperature generates increased thermal motion of an atom that is recorded in the isotropic temperature factor  $B_{\text{eq}}$  of a diffraction experiment. In

**Fig. 11** The temperature dependence of the integral intensity of the  $\text{Fe}^{2+}$  absorption bands. **a** The  $v_1$  and  $v_2$  bands that are related to octahedrally coordinated  $\text{Fe}^{2+}$ ; **b** the  $v_3$  band related to non-octahedral  $\text{Fe}^{2+}$  ( $\beta$ -polarization)

electronic spectra, increased thermal motion is reflected by an increase in the widths of the  $dd$  bands related to the  $3d^N$ -ions. Indeed, the half-width of the  $\nu_3$  band shows a good positive correlation with the  $B_{eq}$  values of the tetrahedral  $T_1$  site (Fig. 12). This behaviour is similar to that of the half-widths of the  $\nu_2$  band and the  $B_{eq}$  values of the octahedral site. The octahedron in cordierite shares two edges with  $T_1$ -tetrahedra (Fig. 1). The good correlation between the half-widths of the  $\nu_3$  bands and the  $B_{eq}$  values for the  $T_1$  site over a range of cordierite compositions is a strong argument in favour of  $Fe^{2+}$  on  $T_1$ . This is, moreover, consistent with a strongly bonded lattice position for the non-octahedral  $Fe^{2+}$  determined on the basis of its Debye temperatures (Vance and Price 1984).

The  $Fe^{2+}Fe^{3+}$  CT band at  $18,000\text{ cm}^{-1}$ , unlike the  $dd$  bands, shows a pronounced decrease in its integral intensity and only slight changes in energy upon heating (Fig. 13, Table 4). This is typical for CT bands (e.g. Smith 1977; Taran and Langer 1998). Spectra obtained on three samples show that the CT band intensity decreases by about one third over the temperature interval 80–700 K. This is in agreement with the data reported for cordierite by Taran and Langer (1998).

$^{57}Fe$  Mössbauer results and their correlation with the electronic absorption spectra: concentrations of the non-octahedral  $Fe^{2+}$

The  $^{57}Fe$  Mössbauer spectra of many natural cordierites display a single  $Fe^{2+}$  doublet with an isomer shift of  $1.31 \pm 0.01\text{ mm s}^{-1}$  at 77 K. This doublet can be assigned

**Fig. 12** Half-widths of the  $Fe^{2+}$  absorption bands as a function of the isotropic temperature factors,  $B_{eq}$ , of the cations in the  $T_1$ -tetrahedral and M octahedral positions. The *sample numbers* correspond to numbers in the tables. *Os* osumilite (Armbruster and Oberhänsli 1988a), *21 T* sekaninaite (no. 21) at 650 K (Hochella et al. 1979). Other structural data were taken from Geiger et al. 2000a (nos. 2, 3) and Hochella et al. 1979 (no. 21)

**Fig. 13** The temperature behaviour of the integral intensity of  $Fe^{2+}Fe^{3+}$  CT band ( $\beta$ -polarization)

to octahedrally coordinated  $Fe^{2+}$  ions (Duncan and Johnston 1974; Goldman et al. 1977; Geiger et al. 2000a). However, in the spectra of some Mg-rich cordierites, with  $X_{Fe}$  below 0.3, two distinct absorption doublets can be observed, thus showing that  $Fe^{2+}$  is located on two different structural sites. Similar results were reported before and the assignment of the second smaller doublet has been debated (Duncan and Johnston 1974; Pollak 1976; Goldman et al. 1977; Vance and Price 1984; Geiger et al. 2000a). No measurable ferric iron doublets were detected in the Mössbauer spectra herein. Therefore, the  $Fe^{3+}$  content in these cordierites cannot be more than about 2–3% of the total iron.

The hyperfine parameters from the MS spectra are listed in Table 5. The effect of temperature, 298 vs. 77 K, is very slight: generally, the area of the smaller doublet increases by only a couple of percentage points at 77 K. Typical spectra are shown in Geiger et al. (2000a). From the known total iron contents and the results of the Mössbauer spectra, the octahedral and non-octahedral  $Fe^{2+}$  fractions were calculated (Table 6). Figure 14 shows that a linear correlation exists between the amount of non-octahedral  $Fe^{2+}$  as determined from the Mössbauer spectra and the integral intensity of the  $\nu_3$  band at  $10,500\text{ cm}^{-1}$ . This indicates that both originate from  $Fe^{2+}$  ions occupying the same structural site. This relationship is used for estimating the non-octahedral  $Fe^{2+}$  amounts for all the cordierites studied here. They vary from 0.2 to 10% of the total iron (Table 6). It should be stated that the electronic absorption spectra of all cordierite samples show bands related to non-octahedral  $Fe^{2+}$ , but only some of them show a corresponding Mössbauer doublet. For those samples which show a single Mössbauer doublet, the amounts of non-octahedral  $Fe^{2+}$  are less than 3%, which would not be detectable by standard Mössbauer methods.

The amount of non-octahedral ferrous iron decreases exponentially with increasing bulk iron (Fig. 15). This is

consistent with cordierite’s crystal-chemical properties (cf. Fig. 5) and explains why a non-octahedral  $\text{Fe}^{2+}$  doublet is observed in magnesium-rich cordierites only (Geiger et al. 2000a).

Ferric iron in cordierite: its location and an estimation of  $\text{Fe}^{3+}/\text{Fe}^{2+}$  ratios

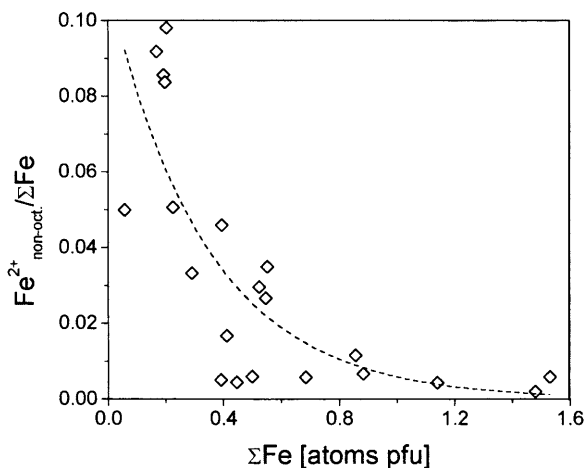

The more recent published data on cordierite show that the  $\text{Fe}^{3+}$  amounts are very small (e.g. Schreyer 1985;

Geiger et al. 2000b). Earlier studies by Pollak (1976) and Parkin et al. (1977) reported the presence of a weak doublet with an isomer shift of about  $0.37 \pm 0.02$  mm s<sup>-1</sup> in Mössbauer spectra, which they assigned to  $\text{Fe}^{3+}$  in tetrahedral coordination.

The variability in the intensity of the  $\text{Fe}^{2+}\text{Fe}^{3+}$  CT band in the electronic spectra obtained herein, even between samples with similar total Fe contents (compare Tables 2 and 3), indicates major differences in the  $\text{Fe}^{3+}/\text{Fe}^{2+}$  ratios of natural cordierites. It is difficult to estimate the  $\text{Fe}^{3+}$  amounts directly, because the molar absorption

**Fig. 14** Integral intensity of the  $\nu_3$  band ( $\gamma$ -polarization) versus the concentration of non-octahedral  $\text{Fe}^{2+}$  as determined by Mössbauer spectroscopy

**Fig. 15** Mole fraction of non-octahedral  $\text{Fe}^{2+}$  calculated from the  $\nu_3$  band intensities using the correlation from Fig. 14 as a function of total iron

coefficient of the CT band is not known. However, one can make a cautious estimation based on the results of the heating experiments. The CT band near  $18,000\text{ cm}^{-1}$  after heating in air increases in intensity, while the  $\nu_3$  band at  $10,500\text{ cm}^{-1}$  decreases and other  $\text{Fe}^{2+}$  absorption bands remain unchanged (Fig. 8). Similar observations were interpreted earlier as indicating the oxidation of the non-octahedral  $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$  that then participates in the  $\text{Fe}^{2+}\text{Fe}^{3+}$  CT interaction (Goldman et al. 1977; Vance and Price 1984). Therefore, it is important to note here that the CT band neither changes its energy, nor polarization after heating. This suggests that the  $\text{Fe}^{3+}$  ions occupy the same structural position before and after heating. Thus, one can estimate the  $\text{Fe}^{3+}$  contents, if the initial amounts of the non-octahedral  $\text{Fe}^{2+}$  and the intensities of both the CT and  $\nu_3$  bands before and after heating are known. This was done using the Mössbauer

data and the electronic spectra obtained on the Kiranur cordierite. It was assumed in a first calculation that all  $\text{Fe}^{3+}$  ions occupy only sites edge-shared with  $\text{Fe}^{2+}$ -centred octahedra and, therefore, are involved in the intervalence CT process. In a second calculation, a random distribution of the ferric ions between the same sites, edge-shared with Mg- or  $\text{Fe}^{2+}$ -centred octahedral, was assumed. The first calculation yields a maximum  $\text{Fe}^{3+}$  content of 0.006 atoms pfu, whereas the second, more reliable one yields 0.001 atoms pfu. The integral intensities of the CT band were normalized to one  $\text{Fe}^{3+}$  ion pfu using both models and the  $\text{Fe}^{3+}$  contents of all the cordierites were determined based on the CT band intensities in their  $\beta$ -polarized spectra. The results give between 0.006 and 0.052  $\text{Fe}^{3+}$  pfu for the first model (Table 6) and between 0.001 and 0.01  $\text{Fe}^{3+}$  pfu for the second one. These values correspond to 0.5–7% of the total iron in the case of an ordered model or to 0.1–1.5% with a random distribution. In about half of the cordierites studied, the CT band is too weak to be resolved accurately. In these cases its intensity and, therefore, the amount of  $\text{Fe}^{3+}$  was assumed to be less than half of that in the unheated Kiranur sample. In both cases, the calculated  $\text{Fe}^{3+}$  amounts in most cordierites are far below the Mössbauer detection limits. No relationship between the  $\text{Fe}^{3+}$  contents and the bulk chemical composition or geological environment was found. This may be related to low-temperature re-equilibration effects that change the  $\text{Fe}^{3+}/\text{Fe}^{2+}$  ratios.

The polarization of the CT band, which is about  $A_{CT\beta}:A_{CT\gamma}=2.7$ , is the same in all the cordierite spectra. It agrees with the theoretically calculated intensity ratio for a CT band caused by an intervalence transition between iron ions located on  $T_{11}$  and the octahedral site (e.g. Smith and Strens 1976; Goldman et al. 1977). No other pair of edge-shared polyhedra can give this polarization of the CT band. Taking into account that most of the  $\text{Fe}^{2+}$  is located on the octahedral site, the  $\text{Fe}^{3+}$  ions must occur on the edge-sharing  $T_{11}$ -tetrahedra. The location of  $\text{Fe}^{3+}$  on  $T_{11}$  is supported by single-crystal EPR measurements (Hedgecock and Chakravartty 1966; Geiger et al. 2000b).

## Final notes

The number and energy of electronic  $\text{Fe}^{2+}$  absorption bands in low-symmetry non-octahedral fields

We have shown that neither the temperature behaviour of the  $\nu_3$  band, nor its decrease in intensity upon heating connected with the corresponding increase in intensity of the  $\text{Fe}^{3+,T_{11}}\text{Fe}^{2+,VI}$  CT band, are consistent with an assignment of  $\text{Fe}^{2+}$  to a channel position. This invalidates the proposal of a six-membered ring channel position (Goldman et al. 1977). If  $\text{Fe}^{2+}$  occupied such a site, it would have a nearly planar coordination in (001) with possible weaker bonds to  $\text{H}_2\text{O}$  molecules above and below (Fig. 1b). In this case, the number and energy of

absorption bands should be compared to the spectroscopic parameters of  $\text{Fe}^{2+}$  in a regular planar coordination rather than to those of the distorted non-centrosymmetric M2 position in pyroxene (see Goldman et al. 1977 for the latter).

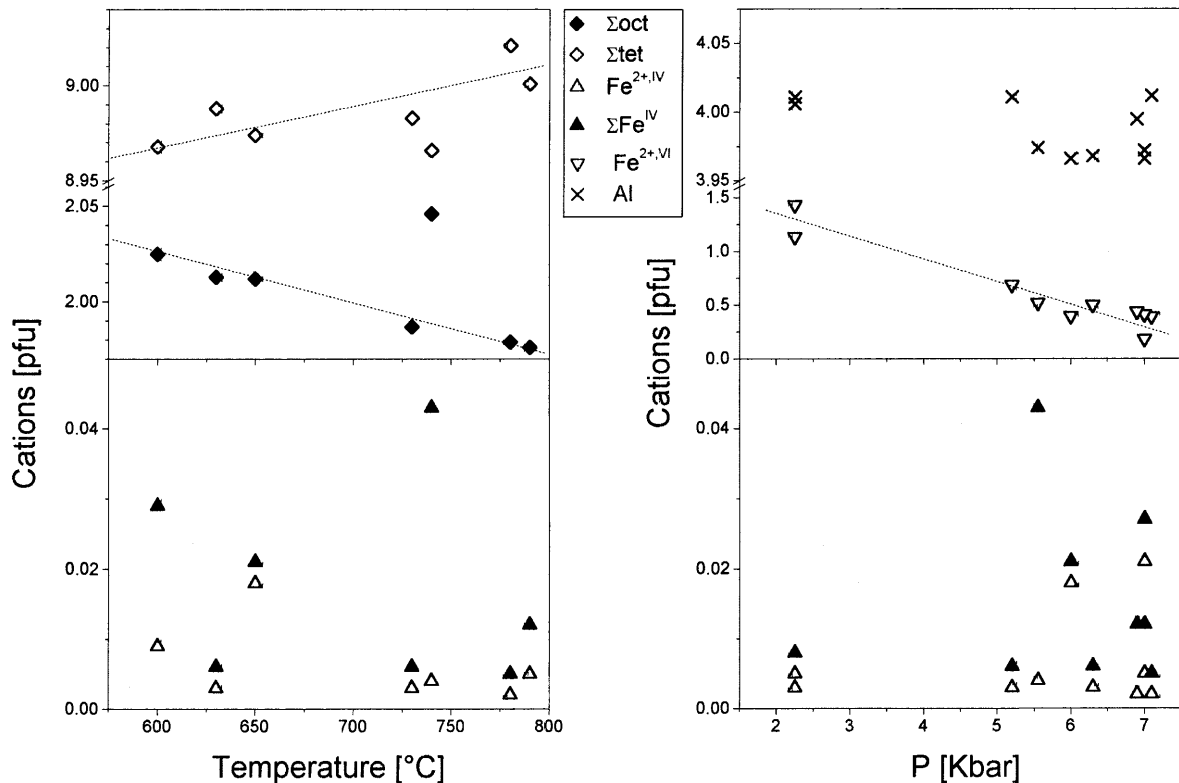

All the spectroscopic and crystal-chemical results presented here provide evidence supporting the allocation of a minor fraction of  $\text{Fe}^{2+}$ , as well as a small amount of  $\text{Fe}^{3+}$ , to the  $T_{11}$  site. Crystal-chemical arguments and the results of the heating experiments support the proposal that the largest  $T_{11}$  tetrahedron is the most probable site for most of the non-octahedral  $\text{Fe}^{2+}$ . This assignment should be consistent with the number, energy and polarization of the observed electronic absorption bands. Therefore, the second and third electronic absorption bands, which must result from the upper split T-level of tetrahedrally coordinated  $\text{Fe}^{2+}$ , as well as the unusually high energy of the  $\nu_3$  band, require consideration.

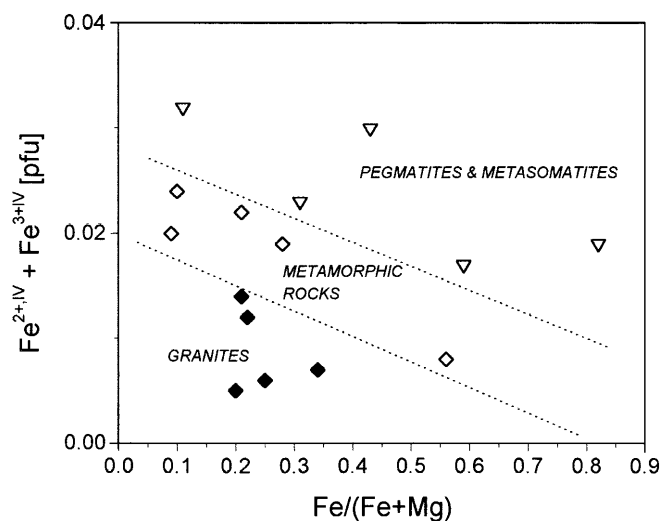

With regards to the number of  $\text{Fe}^{2+,IV}$  bands, two possibilities should be considered, namely: either the weak  $\nu_4$  and  $\nu_5$  bands near  $5,000\text{ cm}^{-1}$  are these wanted bands, or they occur between  $2,000$  and  $1,000\text{ cm}^{-1}$ , where they are superimposed by the high-energy wing of the strong lattice vibration bands. In the first case, the corresponding  $Dq$  value will be  $6,700\text{ cm}^{-1}$ , in the second about  $4,000\text{--}4,500\text{ cm}^{-1}$ . The latter is typical for tetrahedrally coordinated  $\text{Fe}^{2+}$  (e.g. Burns 1993), whereas the

larger  $Dq$  value of  $6,700\text{ cm}^{-1}$  is consistent with the  $T_{11}$ –O distances, smaller than in typical ferrous sites. As for the high energy of the T-level splitting, up to  $9,000\text{ cm}^{-1}$  in the second case, this is known for  $\text{Fe}^{2+,IV}$  in other silicates. Gillespite,  $\text{BaFeSi}_4\text{O}_{10}$ , for example, contains  $\text{Fe}^{2+}$  in square-planar coordination, and it shows an energy separation between the two upper levels of about  $12,000\text{ cm}^{-1}$  (Abu-Eid et al. 1973). The polarization of the  $\nu_3$  band in cordierite requires one principal axis of the local crystal field to be parallel to the  $c$ -axis, which is the case for the  $T_{11}$  site. Thus, the presence of  $\text{Fe}^{2+}$  in the large flattened  $T_{11}$  tetrahedron is consistent with the measured spectroscopic parameters of the  $\nu_3$  band. An exact interpretation of the two weak bands near  $5,000\text{ cm}^{-1}$  remains unclear due to a lack of reliable experimental data. It is likely that the  $\nu_4$  and  $\nu_5$  bands are also related to the non-octahedral  $\text{Fe}^{2+}$  on  $T_{11}$  site.

Generally, just the number of bands in electronic spectra of different minerals, “typically” three for tetrahedrally coordinated  $\text{Fe}^{2+}$  or two for  $\text{Fe}^{2+}$  in octahedral coordination, is not sufficient to assign the absorption bands in the case of low-symmetry non-octahedral fields. There are no straightforward guidelines relating the energy gaps between bands to the site geometry in such cases. For example, the order and energy of electronic levels characteristic of  $\text{Fe}^{2+}$  in square-planar coordination (Burns 1993) can be regarded as an extreme case of an elongated octahedral or flattened tetrahedral field. In such cases, the polarization dependence of the  $dd$  and CT bands, their molar absorptivity and thermal behaviour are the most reliable properties related to the site geometry.

**Fig. 16** Compositional variations in cordierite as a function of the temperature determined by garnet–cordierite thermometry **a** and pressure via geobarometry **b**. For sources of the PT data see Table 1

**Fig. 17** The Fe/(Fe+Mg) ratio versus the total tetrahedral iron contents in cordierite from different geological environments

### Fe<sup>2+</sup> partitioning in cordierite: petrological relevance?

The amount of Fe<sup>2+</sup> on the T<sub>1</sub> site depends on the cordierite composition, particularly on the total Fe content (Fig. 15). When coexisting with other ferromagnesian paragenetic minerals such as garnet or biotite, the Fe/Fe + Mg ratio of cordierite is sensitive to the temperature of equilibration (e.g. Aranovich and Podlesskii 1983). The equilibration temperatures for some of the cordierite samples studied here are known from the literature (Table 1), which permit us to investigate the role of Fe<sup>2+·IV</sup>. Linear correlations are observed between the temperature of equilibration and the number of tetrahedral cations (positive) or the sum of the divalent octahedral cations (negative) (Fig. 16a). The amount of Fe<sup>2+·IV</sup> and the sum of the non-octahedral ferrous and ferric ions, Fe<sup>2+·IV</sup> + Fe<sup>3+·IV</sup>, show a negative correlation versus temperature (Fig. 16a). Scatter is introduced by experimental errors, as well as by the neglecting the effect of Mg<sup>IV</sup>, which could also occupy some of the T<sub>1</sub>-tetrahedra.

The molar volume of cordierite depends mainly on the mole fraction of octahedral Fe<sup>2+</sup> (e.g. Hochella et al. 1979; Wallace and Wenk 1980). This relationship results in a negative linear correlation between pressure of equilibration and Fe<sup>2+·VI</sup> content (Fig. 16b). A decrease in the total iron content is accompanied by a slight decrease in Al and an increase in Fe<sup>2+</sup> on T<sub>1</sub> (Fig. 16b). This leads to Fe<sup>IV</sup> enrichment in cordierites from low-temperature, medium-pressure environments. In plots of X<sub>Fe</sub> versus Fe<sup>IV</sup>, the different cordierites can be defined based on a magmatic, metamorphic or pegmatitic origin (Fig. 17). This plot shows that a decrease in tetrahedral Fe<sup>2+</sup> is related to a temperature increase going from pegmatitic and metamorphic rocks to anatectic granitoids. It can also be seen that Fe<sup>2+·IV</sup> decreases with increasing total iron content (Fig. 15).

The presence of non-octahedral iron affects the Mg–Fe partitioning relationship between coexisting minerals and should be taken into consideration in geothermometry studies. This effect is illustrated for a magnesian-rich cordierite with a Fe<sup>2+·IV</sup> content of 0.02 atoms pfu on the basis of Eq. (5) in Kurepin (1991), which produces a change in the calculated temperature of + 50°.

**Acknowledgements** D. Ackermann, T. Armbruster, S. Herting, V.A. Kurepin, A. Mottana, P. Raase, G.R. Rossman, V. Schenk, A. Speer and D.K. Voznyak generously provided the cordierite samples. F. Galbert, Technical University Berlin, helped with electron microprobe analyses. The German Science Foundation, Bonn-Bad Godesberg, provided research grants to V.M.K. and financial support through Ge 659/6–1 to C.A.G. The optical absorption spectrometers used were made available by the German Science Foundation through La 324/32 to K.L. INTAS, Brussels, contributed generously to the project under 97–32174. To all these individuals and institutions our sincere thanks are due.
