ABSTRACT

Two new quaternary lead oxyhalides, Pb₃MoO₅Cl₂ and Pb₃WO₅Br₂, have been prepared. They are isostructural with the mineral pinalite, Pb₃WO₅Cl₂, and its barium analog. The crystal structure of Pb₃MoO₅Cl₂ has been refined from powder neutron diffraction data to $R_p = 0.0564$ and $R_{wp} = 0.0342$. All these structures contain significantly stretched MO₅ (M = Mo, W) square pyramids incorporated into the [Pb₂O₂] sheets. Bond valence sums indicate significant overbonding of one of the metal sites, which increases along with structural distortions when passing from Pb₃MoO₅Cl₂ to Pb₃WO₅Cl₂ and from Pb₃WO₅Cl₂ to Ba₃WO₅Cl₂. Possibilities of preparing isostructural and structurally related compounds are discussed.

Keywords: Pb₃MoO₅Cl₂, pinalite, crystal structure, neutron diffraction

INTRODUCTION

Lead oxyhalide minerals are common phases that occur in oxidation zones of mineral deposits (Gillberg 1961; Dunn and Rouse 1985; Symes et al. 1994; Welch et al. 2000, etc.). The structures of natural and synthetic lead oxyhalides often exhibit fragments of tetragonal [Pb2O2] layers observed in the structure of litharge, α-PbO (Krivovichev et al. 2004). In some oxygenrich minerals and synthetic compounds, these layers remain as a whole and interleave with halide ion sheets. The interlayer charge balance is provided by two mechanisms, by either substitution of Pb²⁺ by higher-charged cations or diatomic groups, or by substitution of O2- by a lower-charged anion (OH-, F-), or vacancy. These mechanisms can operate both separately, as in the case of perite PbBiO₂Cl (Gillberg 1961) or the oxyfluoride analog of blixite Pb2OFCl (Aurivillius 1977), and simultaneously, as in the case of thorikosite Pb₃SbO₃(OH)Cl₂ (Dunn and Rouse 1985) and freedite Pb₈As₂O₉ CuCl₅ (Pertlik 1987; \Box = oxygen vacancy). All these structures originate from two archetypic subcells corresponding to ideal M2O2X and M4O4X compositions (Fig. 1), and ordering of cations, anions, and/or vacancies result in various superstructures (see Cooper et al, 1994; Welch et al. 1996, 2000, 2001; Welch 2004, as well as references therein).

The substitution of Pb^{2+} by diatomic metal-oxygen groups is common only among oxyhalides of this particular element though it has been once observed for $[M_2L_2]$ layers of other compositions. Most known examples are derived from the structure shown in Figure 1b, the "extra" O atoms protruding into the interlayer space akin to the $Pb_{1-x}(TiO)_xO$ solid solution (Garnier et al. 1990; Cooper et al. 1994; Welch et al. 1996). In the M_2O_2X structure (Fig. 1a), there is very little free space for the "extra" oxygen, the only two known examples being pinalite, Pb₃(WO)O₄Cl₂ (Dunn and Grice 2000, Fig. 2a), and its barium analog, Ba₃WO₅Cl₂ (Spitsyn et al. 1985). The "extra" oxygen of the WO⁴⁺ group is projected into the [Cl⁻] layer pushing the chlorine atoms aside and leaving almost no room for the lone pair of the neighboring lead atom. A related structure of Ca₃WO₅Cl₂ (Zikmund 1974) (Fig. 2b) corresponds to different ordering of Ca²⁺ and WO⁴⁺ and displays particularly significant displacement of chlorine atoms from their ideal positions. This causes essential strain, and it is of interest whether any isostructural or structurally related analogs containing molybdenum and other halogens can exist.

Formation of a compound $Pb_3MoO_5Cl_2$ was detected during an attempt to grow single crystals of Pb_2MoO_5 from $PbCl_2$ flux (Bazarova et al. 1980). However, the observed X-ray pattern was not indexed. As yet, nothing is known about compounds of other halogens. In the current paper, we report the results of our attempts to prepare possible analogs of pinalite among oxyhalides of lead.

EXPERIMENTAL METHODS

The starting compounds were yellow PbO, MoO₃, WO₃, and lead halogenides. The synthetic conditions were the same as in Bazarova et al. 1980. First, Pb₂MoO₅ and PbWO₄ were prepared at 700 °C for 120 h, with one intermediate grinding. Mixtures of Pb₂MoO₃ + PbX₂ or PbWO₄ + PbO + PbX₂ were thoroughly ground and annealed in evacuated silica capsules at 400 °C for 12 h, reground and annealed again at 500 °C (X = Cl, Br) or 400 °C (X = I) for another 12 h. It was soon found that Pb₃MoO₃Cl₂ can also be prepared in covered alumina crucibles in air under the same thermal treatment.

X-ray diffraction patterns were recorded in a Guinier camera FR-552, Enraf-Nonius, and interpreted using a local program and semiconductor quality germanium as an internal standard. Two new compounds isostructural to pinalite, Pb₃MoO₅Cl₂ and Pb₃WO₅Br₂ were found and their diffraction patterns indexed by analogy with orthorhombic cell parameters, a = 11.034(3) Å, b = 13.056(5) Å, c = 5.599(2) Å for Pb₃MoO₅Cl₂ and a = 11.217(3) Å, b = 13.323(3) Å, c = 5.677(2)Å for Pb₃WO₅Br₂. In other cases, mixtures of PbMO₄ (M = Mo, W) and unknown compounds were obtained. The mixture of Pb₂MOO₅ and PbI₂ turned black upon

annealing, which indicates a possible redox reaction. Both oxyhalides decompose above 500 $^\circ\mathrm{C}.$

All attempts to grow single crystals of Pb₃MoO₅Cl₂ from PbCl₂ or CsCl-PbCl₂ fluxes were unsuccessful. It was also found that the X-ray pattern of Pb₃MoO₅Cl₂ changed significantly after the sample came in contact with liquid water even for several minutes. Because a 10 g batch of single-phase Pb₃MoO₅Cl₂, as opposed to Pb₃WO₅Br₂, could be easily prepared, the oxychloride was chosen for structure determination from neutron powder diffraction data.

STRUCTURE DETERMINATION

Neutron powder diffraction data were collected on the high flux diffractometer POLARIS (at 25 °C) at the ISIS facility (Rutherford Lab, Chilton, U.K.) that operates in energy-dispersive (time-of-flight) mode. Approximately 10 g of the sample was placed in a cylindrical vanadium can and data were collected for 1 h. The data from both 145° and 90° detector banks were used for Rietveld analysis employing the GSAS package (von Dreele and Larson 1987).

The starting model was the structure of Pb₃WO₃Cl₂ (Dunn and Grice 2000). The solution converged rapidly to quite low *R* values (Table 1). The final Rietveld refinement plot for the $2\theta = 145^{\circ}$ data set is given in Figure 3. The atomic coordinates are listed in Table 2. Generated bond distances, together with reference data for Pb₃WO₃Cl₂ and Ba₃WO₃Cl₂, are presented in Table 3. We note that the precision of this structure, determined from neutron powder diffraction, is markedly better than that of Pb₃WO₃Cl₂, determined by single-crystal X-ray diffraction (e.g., a factor of 10 improvement in precision for Pb-O and particularly Mo-O bond lengths). This is not surprising due to heavy absorption of X-rays almost exclusively by lead atoms while in neutron diffraction, differences in scattering power of contributing atoms are less pronounced.

RESULTS AND DISCUSSION

Our investigations have added two new representatives to the structure type of pinalite. However, only three of the six possible $Pb_3MO_5X_2$ oxyhalides (M = Mo, W; X = Cl, Br, I) actually exist. This can be explained considering the strain induced by the intrusion of the "extra" oxygen into the relatively dense M2O2X structure. This results in displacement of the halide ions aside from the oxygen, causing concomitant displacements of lead and, finally, oxygen atoms of the [Pb₂O₂] layer away from the transition metal ion. The data given in Table 3 show that the Pb2-Cl bonds are significantly shortened relative to the Pb1-Cl bonds and, additionally, a further bond is formed (Pb2-O2). Bond-valence analysis, performed by the program VaList (Brown and Wills 1999) using parameters from Altermatt and Brown (1985) and Brese and O'Keeffe (1991) reveals that the Pb2 site is seriously overbonded. In fact, the Pb2 bond valence sum calculated by Dunn and Grice (2000) is in error. The true bond valence sums for Pb2 are 2.31 for Pb3WO5Cl2 and 2.32 for Pb₃MoO₅Cl₂, both being significantly above the optimum value of 2 valence units.

These values might be expected to further increase when proceeding to structures containing larger Br⁻ and I⁻ anions, and it is possible that the strain in the hypothetical structure of Pb₃ MoO₃Br₂ exceeds the stability limit of the Pb2 site. Oxyiodides are formed for neither Mo nor W. Replacement of Pb²⁺ by larger Ba²⁺ also increases the overbonding of the M2 site, and it is not yet clear if other alkaline earth analogs can exist. Our preliminary results indicate existence of Ba₃MoO₅Cl₂ isostructural to Ba₃WO₅Cl₂ [*a* = 11.400(3) Å, *b* = 13.919(4) Å, and *c* = 5.766(1) Å], but this compound is very unstable and could not as of yet be prepared in pure form. Attempts to prepare oxybromides and

strontium analogs have so far been unsuccessful. An alternative is the structure of $Ca_3WO_5Cl_2$ where the square-pyramidal WO_5^{2-} geometry is retained, but the coordination number around the Ca^{2+} ions is greatly reduced, to either 5 or 6.

These distortions should disappear or significantly decrease when proceeding to the structure shown in Figure 1b where there is enough free space for the extra oxygen in the interlayer space. A model for the structure of another lead-molybdenum oxychloride, Pb₇MoO₉Cl₂, has been proposed by Welch (1996). This compound is stable enough to occur as a natural mineral parkinsonite (Symes et al. 1994). In fact, all Pb₇MO₉X₂ (M = Mo, W, and X = Cl, Br, I) parkinsonite analogs have been prepared except Pb₇MoO₉I₂ (Aurivillius 1982). The latter is not surprising as Mo^{VI} seems to be reducible by I⁻.

Another way to partially decrease the strain in the Pb_{2-x} (MO)_rO₂X structure is to replace MoO⁴⁺ with higher-charged ReO⁵⁺, which would reduce x down to $\frac{1}{3}$ compared to $\frac{1}{2}$ for $Pb_{1.5}(MoO)_{0.5}O_2X$ (= $Pb_3MoO_5X_2$). Attempts have been made to prepare the corresponding $Pb_{1.67}(ReO)_{0.33}O_2X (\equiv Pb_5ReO_7X_3)$ oxyhalides (X = Cl, Br, I) from $Pb_3O_2X_2$ and $PbRe_2O_8$; X-ray patterns indicated formation of all three target compounds but contained broad lines from which only tetragonal subcell parameters could be estimated. The situation resembles that of schwartzembergite Pb5IO4(OH)2Cl3 (Welch et al. 2001) with the same lead:heteroatom ratio, where only tetragonal substructure could be refined using X-ray diffraction. Despite their preliminary nature, our results on $Pb_5ReO_7X_3$ (X = Cl, Br, and I) clearly indicate the possibility of obtaining even oxyiodides by lowering the content of "extra" O atoms in the M2O2+xX structure. Structural details of the rhenium compounds will be the topic of a separate communication.

As yet, the mechanism of substituting an atom in the $[M_2L_2]$

layers by a diatomic group seems to operate easily only in case of lead (and, possibly, alkaline earth) oxyhalides. Even partial substitution of Pb²⁺ by some ions close in size or electron configuration in the pinalite structure seems to be sufficiently hindered. Though the strain would be evidently reduced by substituting the nine-coordinated (Pb2)²⁺ by Sr²⁺, which has a similar radius but no lone pair, Pb₂SrMoO₅Cl₂ could not be prepared. It is possible that size effects also play an essential role, i.e., while Ba₃WO₅Cl₂ is a complete analog of Pb₃WO₅Cl₂, Ca₃WO₅Cl₂ has a different structure. All attempts to synthesize Pb₂BiNbO₅Cl₂, Bi₃NbO₅Se₂, or Bi₃FeO₅Cl₂ have been unsuccessful.

In conclusion, we were able to prepare Mo and Br analogs of pinalite. Whereas the natural occurence of $Pb_3WO_5Br_2$ is unlikely, Mo-bearing pinalite $Pb_3MOO_5Cl_2$ may be a stable phase in oxidation zones of Pb mineral deposits.
